Elevated intraocular pressure (IOP) in glaucoma causes loss of retinal ganglion cells (RGCs) and damage to the optic nerve. Although IOP is controlled pharmacologically, no treatment is available to restore retinal and optic nerve function. We evaluated the effects of NGF eye drops in a rat model of glaucoma. We also treated 3 patients with progressive visual field defects despite IOP control. Glaucoma was induced in rats through injection of hypertonic saline into the episcleral vein. Initially, 2 doses of NGF (100 and 200 μg/mL) were tested on 24 rats, and the higher dose was found to be more effective. Glaucoma was then induced in an additional 36 rats: half untreated and half treated with 200 μg/mL NGF QID for 7 weeks. Apoptosis/survival of RGCs was evaluated by histological, biochemical, and molecular analysis. Three patients with advanced glaucoma underwent psychofunctional and electrophysiological tests at baseline, after 3 months of NGF eye drops, and after 3 months of follow-up. Seven weeks of elevated IOP caused RGC degeneration resulting in 40% cell death. Significantly less RGC loss was observed with NGF treatment (2.530 ± 121 vs. 1.850 ± 156 RGCs/mm²) associated with inhibition of cell death by apoptosis. Patients treated with NGF demonstrated longitudinal lasting improvements in visual field, optic nerve function, contrast sensitivity, and visual acuity. NGF exerted neuroprotective effects, inhibiting apoptosis of RGCs in animals with glaucoma. In 3 patients with advanced glaucoma, treatment with topical NGF improved all parameters of visual function. These results may open therapeutic perspectives for glaucoma and other neurodegenerative diseases.

**Results**

**Effects of Episcleral Venous Injection of Hypertonic Saline.** At baseline time 0, the mean IOP in SD rats was 24.6 ± 2.1 mm Hg and 24.7 ± 2.2 mm Hg in the control and experimental eyes, respectively. Significant unilateral elevation of IOP was successfully induced in the glaucomatous eyes by saline injection into the episcleral veins (Fig. 1), as shown by mean IOP values measured weekly for 7 weeks starting 1 week after treatment (Fig. 2). Mean IOP in the saline injected eyes was 35.8 ± 3.2 mm Hg, compared to 24.7 ± 2.2 mm Hg in the contralateral, sham operated eyes ($P < 0.01$).

**Effects of Elevated IOP on RGC.** Histological evaluation indicated that compared to normal healthy retinas (Fig. 2B), 7 weeks of chronically elevated IOP induced approximately a 40% decrease in the number of RGCs (Fig. 2C). 1.851 ± 106 RGC/mm² vs. 3.155 ± 98 RGC/mm², respectively, $P < 0.01$, Fig. 2D). To assess whether the reduced RGC number was due to cell death through apoptosis, biomarkers involved in cell death and cell survival were studied. As shown in Fig. 3 A–C, anti-TUNEL staining, a biomarker for apoptotic cell death, was greater in RGCs of rats with elevated IOP compared to healthy controls (6 ± 0.9 vs. 0.4 ± 0.3 per mm², $P < 0.01$). Moreover, molecular analysis of Bcl-2, a biomarker of cell survival, and Bax, a marker of cell death, demonstrated a lower mRNA Bcl-2/Bax ratio in the experimentally induced, untreated glaucomatous eyes (Fig. 3D, Ct values inversely correlated with mRNA expression values). The results of western blot analysis reported in Fig. 3E confirmed the molecular data indicating a lower Bcl-2/Bax protein ratio in glaucomatous eyes.

**Effects of Topical NGF in the Animal Model of Glaucoma.** Preliminary experiments comparing 100 and 200 μg/mL NGF eye drops showed inhibit RGC degeneration after mechanical, ischemic or hypertensive injury (13–15). NGF applied topically to the eye has also been shown to restore sensory nerve function to the ocular surface of patients with neurotrophic keratitis (16). Interestingly, absorption studies have demonstrated that topical ocular NGF reaches the retina, optic nerve, and brain in animals (17, 18).

In the present study, we demonstrate that topical application of exogenous murine NGF to the eye prevents RGC degeneration in an experimental rat model of glaucoma. Based on these findings, we used the same dosage regimen to treat 3 patients with rapid and progressive visual field loss despite successful treatment of ocular hypertension.
a significantly higher biologic effect of 200 μg/mL NGF eye drops in protecting RGC loss in retinal sections from glaucomatous rat eyes, as demonstrated by E/E staining (2,145 ± 102 vs. 2,623 ± 138 RGCs/mm², respectively, P < 0.05). Thus, in subsequent experiments, the 200-μg/mL concentration was used.

Histological analysis showed that topical ophthalmic administration 4 times daily with 200 μg/mL NGF for 7 consecutive weeks protected RGCs of rats with glaucoma (Fig. 4A–H). Specifically, glaucomatous eyes treated with NGF had significantly more RGCs than a parallel group of glaucomatous eyes not treated with NGF (2,530 ± 121 vs. 1,850 ± 156 RGCs/mm², P < 0.01). NGF-treated glaucomatous eyes also had significantly less anti-TUNEL staining of RGCs (1.2 ± 0.6 vs. 0.9 ± 0.9 per mm², P < 0.01), and greater RGC survival, as shown by the significantly higher Bcl-2/Bax ratio (Fig. 4G, Ct values inversely correlated with mRNA expression values). The results of western blot protein analysis confirmed the significantly higher Bcl-2/Bax ratio in NGF-treated glaucomatous eyes, indicating greater RGC survival compared to the RGCs of untreated glaucomatous eyes.

No statistically significant differences were observed between NGF-treated glaucomatous eyes and control eyes in TUNEL staining (1.2 ± 0.6 vs. 0.4 ± 0.3 per mm²) and Bcl-2/Bax ratio. Although RGC cell count showed a protective effect of NGF in glaucomatous eyes, a significantly higher number of RGCs was still observed in control eyes as compared to NGF-treated glaucomatous eyes (3,155 ± 98 vs. 2,530 ± 121, P < 0.05).

Effects of Topical NGF in Patients with Glaucoma. All 3 patients treated with 200 μg/mL NGF showed improvements in psychophysical and electrofunctional parameters after 3 months of treatment. This effect was sustained even after a subsequent 3 months without NGF therapy. The patients with glaucoma had severe dysfunction of the innermost retinal layers and a delay of neural conduction along the postretinal visual pathways, as indicated by PERG P50 and VEP P100 values with longer time-to-peaks and longer RCT and PERG P50-N95 with reduced amplitudes with respect to control data (19). A progressive improvement of inner retinal layer function and postretinal neural conduction was observed during NGF treatment. This enhanced neuronal function was then maintained even 3 months after discontinuation of NGF treatment (Table 1 and Fig. 5).

These electrophysiological changes were accompanied by improvements in clinical parameters as well. Visual field mean defects (MD) improved from 0% to 5% in all patients by the end of NGF treatment (Table 1 and Fig. 6) and a further 1% to 15.8% 3 months after NGF discontinuation.

Contrast sensitivity at 12 cyc/deg in Patient 1 improved from 0.91 (baseline) to 1.080 (15.7%) (end of NGF treatment); in Patient 2, from 0.91 to 1.080 (15.7%), and in Patient 3 from 1.080 to 1.250 (13.6%). These values remained unchanged 3 months after discontinuation of NGF treatment (Table 1).

The best corrected visual acuity in Patient 1 improved from 0.4 to 0.7 (42.8%), in Patient 2, from 0.4 to 0.8 (50%), and in Patient 3 from 0.5 to 0.8 (37.5%). These visual acuity values remained unchanged 3 months after discontinuation of NGF treatment (Table 1).

No side effects were observed during NGF treatment and during the follow-up period, with the exception of a transient (1 week) burning sensation in 1 patient.

Discussion

This study demonstrated that murine NGF administered topically to the eye rescued RGCs from apoptosis in rats. We used a well-characterized experimental model of glaucoma, in which a single injection of hypertonic saline into the episcleral veins of rat eyes induced chronic elevation of IOP, optic-nerve degeneration, and selective RGC loss by apoptosis, the sum effects of which resemble human glaucoma (20–22). The beneficial effect of NGF on RGC survival was demonstrated to be due to inhibition of apoptosis, as shown by the reduction in TUNEL RGC immunostaining and the greater retinal Bcl-2/Bax ratio.

It is known that RGCs express NGF receptor (TrkA) and that NGF binding to TrkA up-regulates Bcl-2 protein, which protects cells from apoptosis by preventing caspase activation (21, 23). Furthermore, intravitreal NGF delivery to the retina and optic nerve is crucial to the survival of RGCs and NGF is known to be responsible for functional recovery of the retina following ocular ischemia and hypertension in animal models (13–15). Lastly, an ophthalmic solution of NGF administered topically to the ocular surface has been shown to reach the retina and optic nerve where it is biologically active (17).
Three months of topical, ocular NGF treatment in 3 patients with advanced glaucoma at risk of vision loss resulted in long-lasting improvement in visual field, contrast sensitivity, and best corrected visual acuity. Despite successful IOP control by medical therapy, these patients had progressive visual field defects and severe abnormalities in PERG and VEP responses that indicated dysfunction of the innermost retinal layers, delay in visual cortical responses, and delay in neural conduction along postretinal visual pathways (24, 25). In glaucoma, up to 20% of patients show progression of visual field defects with RGC and optic nerve degeneration despite successful management of ocular hypertension (26). In fact, elevated IOP is thought to be only the primum movens that triggers a cascade of events leading to optic nerve damage (4). An approach that would vastly improve the treatment of this challenging disease would involve neuroprotection with exogenous neurotrophic factors (6, 27).

PERG and VEP amplitudes and times-to-peak were the first electrofunctional parameters improved in our patients, suggesting a functional recovery of RGCs and an improvement of neural conduction along the postretinal visual pathways. The observed increase in CSV at 12 cyc/deg further supports the efficacy of NGF treatment on RGC (28). These effects are in line with the crucial role of neurotrophins in modulating RGC function and visual cortical neuronal activity reflected by receptive field size, orientation selectivity, visual acuity, response latency, and habituation (29–31).

NGF treatment also improved mean visual field defects in 2 patients (patient 1 and 2), and stabilized the defect in the third patient. Improvement of visual field persisted 90 days after discontinuation of treatment, indicating that changes induced by NGF had a prolonged duration. Two patients were actually followed up after 18 months, at which time improvements in visual field were still stable. This “long-term” NGF effect may be related not only to a protective activity against neural apoptosis, but also to the formation of new neural pathways, since it is known that NGF promotes neural plasticity and axonal regeneration (8, 32–34). In fact, NGF...

Fig. 5. Results of NGF eye drop treatment in 3 glaucomatous patients. Presented are relative changes in the electrophysiological parameters that reflected function of the innermost retinal layer (Panels A and B: pattern electroretinogram: PERG P50 time-to-peak and P50-N95 amplitude, the bioelectric visual cortical response (Panel C: visual evoked potential: VEP P100 time-to-peak) and neural conduction along the postretinal visual pathways (Panel D: retinocortical time: RCT) observed after 30, 60, and 90 days of NGF treatment and after another 90 days of follow-up (time 1, 2, 3, and 6) with respect to the baseline condition (time 0). The relative changes are expressed as percentage increase in amplitude or percentage decrease in time-to-peak from baseline. Percentage increases in PERG P50-N95 amplitude and percentage decreases in PERG P50 time-to-peak indicated a reduction in ganglion cell dysfunction after NGF treatment. Percentage decreases in VEP P100 time-to-peak and percentage decreases in RCT indicated a reduction of the neural conduction delay along visual pathways after NGF treatment.

Table 1. Effects of NGF treatment in 3 patients affected by advanced glaucoma

- NGF acts on numerous levels to promote neuronal recovery following ischemic and chemical injuries: through a neosynaptogenetic mechanism, by directly affecting precursor cells and/or by induction of other growth factors, including BDNF (8, 35–37). These multiple activities may cause the progressive improvement in visual acuity observed in our 3 patients during and after NGF treatment (Table 1).

- The neuroprotective effects of NGF in glaucoma demonstrated in this study, together with the recently gained knowledge of NGF’s ability to reach the brain when topically administered to the eye, allude to exciting possibilities for the treatment of neurodegenerative diseases of the central nervous system (18, 38). A major challenge in treating neurodegenerative disorders such as Alzheimer’s disease has been the difficulty of delivering neurotrophic factors across the blood-brain barrier (8). This obstacle might be overcome by ophthalmic topical NGF treatment, and absorption and diffusion studies following this premise should be undertaken.

- Many similarities between glaucoma and Alzheimer’s disease go far beyond the challenges encountered in their treatment: (i) RGCs die by apoptosis in glaucoma through activation of specific caspases, which are also activated in Alzheimer’s; (ii) caspase activation with cleavage of APP has been shown to up-regulate amyloid-beta production in Alzheimer’s and in animal models of glaucoma; (iii) age-related mitochondrial dysfunction plays a key role in the etiology of both neurodegenerative disorders; (iv) elevated glutamate and nitric oxide synthase up-regulation with reactive oxygen species formation have been implicated in both glaucoma and Alzheimer’s neurotoxicity; and (v) glutamate toxicity is involved in both glaucoma and Alzheimer’s synaptic dysfunction (39, 40). All of these similarities have led glaucoma to be dubbed the “ocular Alzheimer’s disease” (39). The obvious benefit to this likeness is the combining of forces in identifying new strategies to treat either disease.

- In summary, this study indicates that topical NGF treatment may be an effective adjunct therapy for glaucoma, reducing neuron death and nerve loss. These encouraging results merit further investigation of topical NGF in controlled clinical trials in glaucoma and other forms of neurodegenerative disorders.
Materials and Methods

For this study, we used pathogen-free, adult male Sprague-Dawley (SD) rats (n = 78) maintained on a 12-h light-dark cycle and provided with food and water ad libitum. All procedures regarding housing, care and experimental procedures were carried out following the guidelines of the ARVO Statement for the Use of Animals in Ophthalmic and Vision Research, International law (ECC council directive 86/609, OJ L 358, 1, December 12, 1987), and the Italian National Research Council’s Ethical Commission on Animal Experimentation (1992).

Preliminary histological studies aimed to identify the best NGF concentration were performed on 24 rats: 6 untreated normal rats (control group), 6 untreated rats with glaucoma, 6 100 μg/mL NGF-treated rats with glaucoma, and 6 200 μg/mL NGF-treated rats with glaucoma. Briefly, retinal sections were fixed for 3 days in phosphate buffer containing 10% sucrose, pH 7.4. Retinal sections 20 μm in width were cut with a cryostat at 4 °C, and stained with hematoxylin-eosin. Using ImageJ image processing and analysis software, RGCs were counted in a masked fashion in 4 quadrants of the retinal sections approximately 2 mm from the center of the optic disc. Counts were taken from comparable areas under a Zeiss Microscope at 400× magnification. The results were averaged and converted to cells per mm².

Analysis of Cell Death. For the determination of RGC death and survival, sections of the retina were immunostained with TUNEL (TdT-dUTP Terminal Nick-End), a marker of apoptotic cell death, combined with western blot and molecular analysis. Briefly, retinal sections were first incubated in a blocking solution (3% H₂O₂ in methanol) for 10 min at 15–25 °C, incubated in a permeabilization solution containing 1× PBS 0.1% Triton X-100 for 2 min at 4 °C, and then labeled with an in situ cell death detection kit (Roche Diagnostic, Boheringer) according to the manufacturer’s instructions. For TUNEL-positive cells, DNA strand breaks were labeled and visualized with 0.4% DAB-H₂O₂. TUNEL-positive cells with nuclear condensation or fragmentation were considered as apoptotic cells.

For Bcl-2 and Bax western blot experiments, protein concentrations were determined using the Micro BCA protein assay kit. After determination of protein concentrations, equivalent amounts of retinal lysates (50 μg) were denatured in sample buffer (final concentration of 2% SDS, 10% glycerol, and 2% 2-mercaptoethanol, pH 6.8) and electrophoresed through 10% denaturing polyacrylamide gels. Following SDS-polyacrylamide gel electrophoresis, samples were transferred electrophoretically to nitrocellulose membranes in transfer buffer. Membranes were blocked for 1 h in 1% TBS/0.1% Tween-20 with 5% defatted milk powder. Anti-Bcl-2 and anti-Bax primary antibodies (Santa Cruz Biotechnology) were incubated with the appropriate membranes at a dilution of 1:500 overnight. The GAPDH primary antibody (Sigma) was used at a dilution of 1:15,000. Appropriate HRP-conjugated secondary antibodies, all diluted to 1:2,500, were incubated with the membranes for 1 h. After incubation with secondary antibody, membranes were washed 3 times in 1× TBS (pH 7.4) with 1% Tween-20, and then developed using chemiluminescence. Images were digitalized in a Kodak Imager Station and bands were subjected to densitometric analysis using 1D Kodak software.

Molecular Analysis/Real-time PCR. Bcl-2 and Bax mRNA were measured in rat retinas (average 0.010 mg wet weight for each sample). Tissues were pretreated with proteinase K (20 μg/mL, Finzyme) in HIRT buffer at 56 °C/3 h, and total RNA was extracted from samples using the Puregene RNA purification kit (Genter Systems). The resulting total RNA was re-suspended in 25 μL diethyl pyrocarbonate-treated water (ICN) and treated with RNase-Free DNase I to eliminate any genomic DNA contamination according to the supplier’s protocol (2 U/μL Turbo DNA free kit AM-1907, Ambion Ltd.). Total RNA samples were checked for both RNA quantity (NanoDrop; Cellbio, purity (1.6) and absence of any RNA degradation (RIN > 8). Equivalent amounts of RNA (3 μg) per sample were used as a template in normalized cDNA synthesis. Reverse transcription was performed according to the standardized Mu-MLV protocol (final volume reaction of 20 μL using 50 pM oligo dT-primer, 1 mM dNTP mix, and 200 U reverse transcriptase; Mu-MLV, F-605L; Finnzyme) in a PTC-100 programmable thermocycler (MJ Research). The resulting cDNA was amplified using the SYBR Green PCR core reagent kit (Applied Biosystems) and an Opticon2 MJ Research system (MJ Research). The reaction contained 10 μL SYBR reagent, 3 μL cDNA (for the target) or 1 μL cDNA (for the referring gene), and 20 nM primers in a 20-μL final volume. The temperature profile included initial denaturation at 95 °C/15 min, followed by 35–47 cycles of denaturation at 95 °C/30 s, annealing at 55–60 °C/20 s (the annealing time depended on the primer’s Tm), elongation at 72 °C/30 s, fluorescence monitoring at 60–90 °C, and further incubation at 72 °C/5 s. Specific previously published primers for Bcl2 were used for this study (21). Primer specificities were further confirmed by the single melting curves obtained during each amplification. Negative controls (without template) were produced for each run. Experiments were performed in duplicate for each data point. Quantitative values were obtained from the threshold cycle value (Ct), which is the point where a significant increase of fluorescence is first detected. According to the REST software, results are expressed as N-fold difference (increase or decrease) in target gene expression. Generally, ratios between Bcl-2/Bax were calculated according to the single Ct values.

NGF Eye Drop Preparation and Treatment. NGF was obtained from murine salivary glands as previously described, following the Bocchini and Angeletti method (41). Briefly, gel filtration at pH 7.5 was performed on the aqueous gland extract of adult mice, followed by dialysis at pH 5.0 and fractionation by cellulose chromatography. In the present study, the biologically active form of highly active.
purified murine NGF weighing 26 kDa was used, dissolved in a sterile 0.9% NaCl solution at 2 different concentrations (100 and 200 µg/mL) (17).

**Selection of Patients.** Three patients (69 ± 6 years old, 2 males and 1 female) affected by advanced and progressive glaucoma (disease duration 21 ± 9 years), with impending risk of vision loss, despite good pharmacological control (timolol 0.5% applied 2 times a day in a fixed combination BID and latanoprost QID) of intraocular pressure (measured by applanation tonometry) were included in the study. Advanced glaucoma was defined by the following functional criteria: a mean deviation less than −24 dB, the presence of only a central or temporal island remaining in the visual field gray scale (42); and optic disk rim deterioration as an additional morphological criterion (43).

**Treatment Regimen in Patients with Glaucoma.** Based on the dosage regimen used in the animal model, the 3 patients were treated topically with 1 drop (~50 µL) of highly purified murine NGF, 200 µg/mL, instilled into the conjunctival fornix of 1 eye only 4 times daily for 3 months.

The tenets of the Declaration of Helsinki were followed in this study. Informed consent was obtained from the subjects after explanation of the nature and possible consequences of the study. All patients were at imminent risk of irreversible and complete vision loss for uncontrolled progression of glaucoma despite adequate IOP control and were, therefore, treated on a compassionate basis.

**Evoked Potential Measurements.** Electroretinography (EgO) was performed at baseline, every month during treatment and 3 months post-therapy by means of a commercially available system (CSEEK, Littech). Transient VEP was characterized by 3 peaks that appeared after 35, 50, and 95 ms and had negative (N35), positive (P50), and negative (N95) polarity, respectively. Amplitudes (in µV) and time-to-peaks (in ms) were measured. Simultaneous recordings of VEPs and PEGs identified an index of neural conduction along the postretinal visual pathways, defined as retinocortical time (RCT), the difference between the VEP P100 and the PEG P50 time-to-peak.

**Data Analysis.** Statistical analysis was performed using the SuperANOVA package for Macintosh (Abacus Concepts Inc.) and the Tukey-Kramer comparison; a P value of less than 0.05 was considered statistically significant. Animal data of control groups were compared and reported at endpoint. While the group of 3 patients was too small to elucidate statistically, the data presented are individual changes over time from baseline.

**ACKNOWLEDGMENTS.** This work was supported by Italian Ministry of Health Grant RF-FGB-2005-625675, Italian Ministry of University and Scientific Research Grant 2007A3FX3H4, and an unrestricted research grant from Fondazione Rome.
